METHODS AND COMPOSITIONS FOR GENE THERAPY FOR THE
TREATMENT OF DEFECTS IN LIPOPROTEIN METABOLISM

This invention was supported by the National Institute of Health Grant Nos. DK 42193-05 and HD 29946.

- 5 The United States government has rights in this invention.

Field of the Invention

The present invention relates to the field of somatic gene therapy and the treatment of genetic 10 disorders related to lipoprotein metabolism.

Background of the Invention

The metabolism of lipids, particularly cholesterol, involves the interaction of a number of lipoproteins and apolipoproteins. Very low density 15 lipoprotein (VLDL) and apolipoprotein E (apoE) are key precursor molecules in the production of low density lipoprotein (LDL) and in the overall metabolism of lipids, including cholesterol. LDL is the major cholesterol-transport lipoprotein in human plasma.

20 The VLDL/apoE receptors are expressed in heart, skeletal muscle, and adipose tissue [F. M. Wittmaack et al, *Endocrinol.*, 136(1):340-348 (1995)] with lower levels of expression in the kidney, placenta, pancreas, and brain. This receptor has been suggested to play a role 25 in the uptake of triglyceride-rich lipoprotein particles by specific organs. The cDNA encoding the putative human VLDL receptor was recently cloned [M. E. Gafvels et al, *Som. Cell Mol. Genet.*, 19:557-569 (1993), incorporated by reference herein]. The receptor for LDL is located in 30 coated pits on the surfaces of cells in the liver and other organs.

As depicted in Fig. 1A, in a normal healthy human, the molecules apolipoprotein B48 (Apo-B48), apolipoprotein C-II (Apo-C-II) and Apo E form a

chylomicron particle in plasma passing through the intestines, which interacts with a chylomicron remnant receptor in the liver. After metabolism of the chylomicrons taken up by the remnant receptor, the liver produces the primary lipoprotein, VLDL, which contains Apo-E, Apo-C-II and apolipoprotein B100 (Apo B100). VLDL is metabolized into LDL, which binds to the LDL receptor in the liver via Apo B100. The LDL receptor in the liver facilitates the uptake of LDL by receptor-mediated endocytosis. LDL is degraded in lysosomes, and its cholesterol is released for metabolic use.

Defects in the metabolism of such lipoproteins and/or receptors result in several serious metabolic disorders. The human disease familial hypercholesterolemia (FH) is caused primarily by one or more mutations in the gene encoding the LDL receptor. FH is characterized clinically by (1) an elevated concentration of LDL; (2) deposition of LDL-derived cholesterol in tendons and skin (xanthomas) and in arteries (atheromas); and (3) inheritance as an autosomal dominant trait with a gene dosage effect. Individuals with FH develop premature coronary heart disease, usually in childhood. Heterozygotes number about 1 in 500 persons, placing FH among the most common inborn errors of metabolism. Heterozygotes have twofold elevations in plasma cholesterol (350 to 550 mg/dl) from birth and tend to develop tendon xanthomas and coronary atherosclerosis after age 20. Homozygotes number 1 in 1 million persons and are characterized by severe hypercholesterolemia (650 to 1000 mg/dl), cutaneous xanthomas which appear within the first 4 years of life, and coronary heart disease which begins in childhood and frequently causes death before age 20. [J. Goldstein et al, "Familial Hypercholesterolemia", Chapter 48, in The Metabolic Basis of Inherited Disease, 6th ed., C. R. Scriver et al

(eds), McGraw-Hill Information Services Co., NY, NY, (1989) pp. 1215-1250].

Another metabolic disorder is familial combined hyperlipidemia (FCH) which was first associated with 5 hyperlipidemia in survivors of myocardial infarction and their relatives. FCH patients generally have one of three phenotypes: (1) elevated levels of VLDL, (2) elevated levels of LDL, or (3) increases in the levels of both lipoproteins in plasma. Unlike FH, FCH appears in 10 only 10 to 20 percent of patients in childhood, usually in the form of hypertriglyceridemia. Homozygosity for the trait may result in severe hypertriglyceridemia. [J. Goldstein et al, "Disorders of the Biogenesis and Secretion of Lipoproteins", Chapter 44B in The Metabolic 15 Basis of Inherited Disease, 6th ed., C. R. Scriver et al (eds), McGraw-Hill Information Services Co., NY, NY, (1989) pp. 1155-1156]. This disorder is also associated with the appearance of glucose intolerance and obesity in a number of individuals.

20 The most striking abnormality of FCH is marked elevation of VLDL content of plasma. Increased production of VLDL leads to an expanded plasma pool of VLDL in some individuals, but in others with more efficient lipolysis, it results in increased levels of 25 LDL. FCH is characterized by an excess production of LDL, rather than a genetic defect in the LDL receptor. The LDL receptors of cultured fibroblasts appear to be normal in FCH patients.

Clinical experience suggests that FCH is at 30 least five times as prevalent as FH, occurring in about 1 percent of the North American population. The predilection toward coronary artery disease among patients with this disorder makes it the most prominent known metabolic cause of premature atherosclerosis [J. 35 Goldstein et al, cited above].

When *LDL* receptors are deficient as in FH (see Fig. 1B), or excess *LDL* is produced due to excess *VLDL* as in FCH, the efficient removal of *LDL* from plasma by the liver declines, and the level of *LDL* rises in inverse proportion to the receptor number. The excess plasma *LDL* is deposited in connective tissues and in scavenger cells, resulting in the symptoms of either disorder.

Presently, treatment for FH and FCH is directed at lowering the plasma level of *LDL* by the administration of drugs, i.e., combined administration of a bile acid-binding resin and an inhibitor of 3-hydroxy-3-methylglutaryl CoA reductase for treatment of FH and niacin for treatment of FCH. However, FH homozygotes with two nonfunctional genes are resistant to drugs that work by stimulating *LDL* receptors. Similarly, such drugs are not particularly effective in FCH. In FH homozygotes, plasma *LDL* levels can be lowered only by physical or surgical means.

Administration of normal *LDL* receptor genes by gene therapy using an adenovirus vector has been contemplated for the treatment of FH. Adenovirus vectors are capable of providing extremely high levels of transgene delivery to virtually all cell types, regardless of the mitotic state. The efficacy of this system in delivering a therapeutic transgene *in vivo* that complements a genetic imbalance has been demonstrated in animal models of various disorders [K. F. Kozarsky et al, Somatic Cell Mol. Genet., 19:449-458 (1993) ("Kozarsky I"); K. F. Kozarsky et al, J. Biol. Chem., 269:13695-13702 (1994) ("Kozarsky II"); Y. Watanabe, Atherosclerosis, 36:261-268 (1986); K. Tanzawa et al, FEBS Letters, 118(1):81-84 (1980); J.L. Golasten et al, New Engl. J. Med., 309:288-296 (1983); S. Ishibashi et al, J. Clin. Invest., 92:883-893 (1993); and S. Ishibashi et al, J. Clin. Invest., 93:1885-1893 (1994)]. The use

of adenovirus vectors in the transduction of genes into hepatocytes *in vivo* has previously been demonstrated in rodents and rabbits [see, e.g., Kozarsky II, cited above, and S. Ishibashi et al, J. Clin. Invest., 92:883-893 (1993)].

Recent research has shown that introduction of a recombinant adenovirus encoding the human *LDL* receptor ("LDLR") cDNA into the livers of *LDL* receptor-deficient Watanabe heritable hyperlipidemic (WHHL) rabbits, which mimic the condition of FH, resulted in large, transient reductions in plasma cholesterol. The transient nature of the effect of recombinant adenoviruses in most situations is attributed to the development of cellular immune responses to the virus-infected cells and their subsequent elimination. Antigenic targets for immune mediated clearance are viral proteins expressed from the recombinant viral genome and/or the product of the transgene, which in this case, is the *LDL* receptor protein [Y. Yang et al, Proc. Natl. Acad. Sci., USA, 91:4407-4411 (May 1994); Y. Yang et al, Immun., 1:433-442 (August 1994)].

Additionally, repeated reinfusions of the LDLR gene-containing adenovirus did not produce similar, subsequent cholesterol reductions due to the development of neutralizing anti-adenovirus antibodies [Kozarsky I and Kozarsky II, cited above; see also Y. Yang et al, Immun., 1:433-442 (August 1994), all incorporated by reference herein].

There remains a need in the art for therapeutic compositions and gene therapy strategies which enable effective treatment and/or prevention of FH and FCH, as well as other defects in lipoprotein metabolism.

Summary of the Invention

In one aspect, the invention provides a recombinant viral vector comprising the DNA of, or corresponding to, at least a portion of the genome of an adenovirus, which portion is capable of infecting a hepatic cell; and a human VLDL receptor ("VLDLR") gene operatively linked to regulatory sequences directing its expression, the vector capable of expressing the VLDLR gene product in the hepatic cell *in vivo* or *in vitro*.

10 In another aspect, the invention provides a mammalian cell infected with the viral vector described above.

15 In still a further aspect, the invention provides a method for delivering and stably integrating a VLDLR gene into the chromosome of a mammalian hepatocyte cell comprising introducing into said cell an effective amount of a recombinant viral vector described above.

20 Another aspect of this invention is a method for treating a patient having a metabolic disorder comprising administering to the patient by an appropriate route an effective amount of an above described vector containing a normal VLDLR gene, wherein said VLDLR gene is integrated into the chromosome of said patient's hepatocytes and said receptor is expressed stably *in vivo* at a location in the body where it is not normally expressed.

25 Other aspects and advantages of the present invention are described further in the following detailed description of the preferred embodiments thereof.

30 Brief Description of the Drawings

Fig. 1A is a schematic drawing of normal human and rabbit lipoprotein metabolism. The apolipoproteins are referred to as B48, B100, C-II, and E. LDL and VLDL are identified.

Fig. 1B is a schematic drawing of lipoprotein metabolism in FH patients and WHHL rabbits. The abbreviations are as described in Fig. 1A.

5 Fig. 1C is a schematic drawing of lipoprotein metabolism in rabbits infused with the recombinant VLDLR gene according to the invention.

Fig. 2 is a schematic drawing of plasmid pAd.CMVVLDLR, which contains adenovirus map units 0-1 (Ad 0-1), followed by a cytomegalovirus enhancer/promoter 10 (CMV enh/prom), a human VLDLR gene, a polyadenylation signal (pA), adenovirus map units 9-16 (Ad 9-16) and plasmid sequences from plasmid pAT153 including an origin of replication and ampicillin resistance gene. Restriction endonuclease enzymes are represented by 15 conventional designations in the plasmid construct.

Fig. 3 is a schematic map of recombinant adenovirus H5.010CMVVLDLR, in which 0 to 100 represent the map units of an adenovirus type 5 (Genbank Accession No. M73260), and the CMV/VLDLR/pA minicassette of 20 pAd.CMVVLDLR is inserted between adenovirus map units 1 and 9, with the remaining Ad5 map units 9-100 having a partial E3 gene deletion between about map unit 78.5 and about 84.3.

Fig. 4A is a graph plotting changes in plasma 25 cholesterol levels in mg/dl for WHHL rabbits as a function of days before and after receiving recombinant adenovirus H5.010CMVlacZ. The symbols represent individual animals. See Example 3.

Fig. 4B is a graph plotting changes in plasma 30 cholesterol levels in mg/dl for WHHL rabbits as a function of days before and after receiving recombinant adenovirus H5.010CMVVLDLR. The symbols represent the response of four individual animals. See Example 3.

Fig. 5 is a bar graph representing cholesterol levels (measured as % pre-infusion) in mice infused with recombinant adenovirus H5.010CMVlacZ (lacZ), recombinant adenovirus H5.010CMVLDLR and recombinant adenovirus H5.010CBhLDLR. The dotted bars represent pre-infusion levels and the solid bars represent post-infusion levels. See Example 4.

Fig. 6 is a bar graph representing cholesterol levels, specifically the levels of the fractions of plasma lipoproteins (measured as mg/fraction) in mice infused with recombinant adenovirus H5.010CMVlacZ (lacZ), recombinant adenovirus H5.010CMVLDLR and recombinant adenovirus H5.010CBhLDLR. The solid bars represent proteins or fragments falling within a density (d) $>$ 1.21; the thickly cross-hatched bars represent HDL; the closely cross-hatched bars represent LDL, the spaced apart slanted hatched bars represent intermediate density lipoprotein (IDL), and the clear bars represent VLDL levels. See Example 4.

Fig. 7A is a graph plotting changes in cholesterol levels (measured in mg/dl) as a function of days pre- and post-infusion for mice infused with H5.010CMVlacZ. The symbols represent the responses of individual animals. See Example 5.

Fig. 7B is a graph plotting changes in cholesterol levels (measured in mg/dl) as a function of days pre- and post-infusion for mice infused with H5.010CBhLDLR. The symbols are the same as for Fig. 7A. See Example 5.

Fig. 7C is a graph plotting changes in cholesterol levels (measured in mg/dl) vs. days pre and post-infusion for mice infused with H5.010CMVLDLR. The symbols are the same as for Fig. 7A. See Example 5.

Fig. 7D is a graph providing the average results \pm standard deviation from two experiments for mice infused with H5.010CMVLacZ ($n=9$) or with H5.010CMVLDLR ($n=10$). Average pre-infusion cholesterol levels were 870 mg/dl and 946 mg/dl, respectively. Asterisks indicate $p < 0.05$.

Figs. 8A-8F are the DNA sequence [SEQ ID NO: 1] with encoded amino acid sequence [SEQ ID NO: 2] of the human VLDL receptor gene, as reported by Gafvels et al, cited above.

Figs. 9A-9I are the DNA sequence of pAd.CMVLDLR [SEQ ID NO: 3], in which Ad 0-1 spans nucleotides 12-364, CMV ehn/prom spans nucleotides 381-862; nucleotides 966-4107 encode VLDLR, pA spans 15 nucleotides 4192-4390; Ad 9.2-16.1 span nucleotides 4417-6880 and nucleotides 6881-9592 are pAT153 sequences.

Fig. 10A is a bar chart illustrating the CTL activity (average \pm standard deviation) measured at an effector:target cell ratio of 25:1. ** = $p < 0.005$; * = 20 $p < 0.05$.

Fig. 10B is a line graph illustrating the CTL activity measured against varying effector:target ratios.

Fig. 11A is a graph summarizing neutralizing antibody titer present in BAL samples of C57BL/6 mice 25 adenovirus-infected on day 0 and necrotized on day 28 as described in Example 9. Control represents normal mice ("control"); CD4 mAB represents CD4 $^{+}$ cell depleted mice; IL-12 represents IL-12 treated mice and IFN- γ represent IFN- γ treated mice.

30 Fig. 11B is a graph summarizing the relative amounts (OD_{405}) of IgG present in BAL samples. The symbols are as described in Fig. 11A.

Fig. 11C is a graph summarizing the relative amounts (OD_{405}) of IgA present in BAL samples. The 35 symbols are as described in Fig. 11A.

Detailed Description of the Invention

The present invention provides novel compositions and methods which enable the therapeutic treatment of metabolic disorders, such as FH and FCH, 5 characterized by the accumulation of LDL in human plasma. This invention provides for the use of a viral vector to introduce and stably express a gene normally expressed in mammals, i.e., the gene encoding a normal receptor for very low density lipoprotein (VLDLR), in a location in 10 the body where that gene is not naturally present, i.e., in the liver.

The methods and compositions of the present invention overcome the problems previously identified in the gene therapy treatment of LDL receptor-deficient 15 individuals. As described in detail below, by use of a viral vector capable of targeting cells of the liver, the VLDL receptor gene is introduced into and stably expressed in liver cells. The present invention differs from direct gene replacement in that the VLDL receptor 20 protein is expressed normally in LDL receptor deficient individuals, e.g., the macrophages. Thus, gene therapy using a liver-directed viral vector carrying a VLDLR gene would result not in expression of a new gene product, but rather, in *de novo* expression in an organ which otherwise 25 does not express the gene product. Importantly, the patient does not mount an immune response against the VLDLR gene product expressed in the liver because the vector-delivered VLDLR gene is not recognized as a foreign antigen, and there is no induction of CTL-mediated elimination of the transfected cell. In 30 contrast, CTL-mediated elimination of viral vectors is a problem when an LDLR gene is administered to an LDLR-deficient individual with FH [see, e.g., Kozarsky I and II, cited above].

Due to this recognition of the *VLDLR* gene by the patient's immune system as a known gene, and to the tendency of hepatocytes to have a long life in circulation, the hepatocytes transfected with the vector of this invention, which express the *VLDLR* gene, tend to be stable and *VLDLR* expression is not transient. *VLDLR* gene expression in transfected hepatocytes occurs for the duration of the hepatocyte's life. The lipoprotein metabolic disorder may be treated for longer times without the need for reinfusing the viral vector, thus limiting the number of viral exposures and potential immune reactions to vector-encoded viral proteins.

The vectors and methods of this invention can provide gene therapy useful to treat and/or supplement current treatments for lipoprotein metabolic disorders. The presence of the *VLDL* receptor gene in the transfected hepatocytes according to this invention permits the binding of *VLDL*, a precursor of *LDL*, from the plasma at the site of the liver, thereby decreasing the amount of *VLDL* in plasma. The decrease in *VLDL* in the plasma consequently decreases the production of plasma *LDL*.

For example, in FH, this reduction in plasma *LDL* can compensate for the defective *LDL* receptors in the liver. In FCH, this reduced production of plasma *LDL* from *VLDL* prevents the normal *LDL* receptors in the liver from becoming overloaded by excess *LDL*, and reduces the excess *VLDL* which contributes to the disorder. Compare, for example, the schematic representations of the normal operation of lipid metabolism (Fig. 1A) to the abnormal metabolism caused by FH (Fig. 1B) and then to the method of this invention (Fig. 1C).

I. Recombinant Viral Particles as Gene Therapy
Vectors

The compositions of this invention involve the construction of desirable gene therapy vectors, which are capable of delivering and stably integrating a functional, normal VLDL receptor gene to hepatocytes. Such gene therapy vectors include a selected virus vector, desirably deleted in one or more viral genes, a minigene containing the VLDLR gene under the control of regulatory sequences, and optional helper viruses and/or packaging cell lines which supply to the viral vectors any necessary products of deleted viral genes.

The viral sequences used in the vectors, helper viruses, if needed, and recombinant viral particles, and other vector components and sequences employed in the construction of the vectors described herein are obtained from commercial or academic sources based on previously published and described sequences. These viral materials may also be obtained from an individual patient. The viral sequences and vector components may be generated by resort to the teachings and references contained herein, coupled with standard recombinant molecular cloning techniques known and practiced by those skilled in the art. Modifications of existing nucleic acid sequences forming the vectors, including sequence deletions, insertions, and other mutations taught by this specification may be generated using standard techniques.

The methods employed for the selection of viral sequences useful in a vector, the cloning and construction of VLDLR "minigene" and its insertion into a desired viral vector and the production of a recombinant infectious viral particle by use of helper viruses and the like are within the skill in the art given the teachings provided herein.

A. Construction of the "Minigene"

By "minigene" is meant the combination of the VLDLR gene and the other regulatory elements necessary to transcribe the gene and express the gene product *in vivo*. The human VLDL receptor sequence has been provided [see, Gafvels et al, cited above; SEQ ID NOS: 1 and 2]. Generally, the entire coding region of this receptor sequence is used in the minigene; the 5' and 3' untranslated sequences of SEQ ID NO: 1 are not essential to the minigene. VLDL receptor genes of other mammalian origins, e.g., rabbit, monkey, etc., may also be useful in this invention.

The VLDL receptor gene (VLDLR) is operatively linked to regulatory components in a manner which permits its transcription. Such components include conventional regulatory elements necessary to drive expression of the VLDLR transgene in a cell transfected with the viral vector. Thus the minigene also contains a selected promoter which is linked to the transgene and located, with other regulatory elements, within the selected viral sequences of the recombinant vector.

Selection of the promoter is a routine matter and is not a limitation of this invention. Useful promoters may be constitutive promoters or regulated (inducible) promoters, which will enable control of the amount of the transgene to be expressed. For example, a desirable promoter is that of the cytomegalovirus immediate early promoter/enhancer [see, e.g., Boshart et al, Cell, 41:521-530 (1985)]. Another desirable promoter includes the Rous sarcoma virus LTR promoter/enhancer. Still another promoter/enhancer sequence is the chicken cytoplasmic B-actin promoter [T. A. Kost et al, Nucl. Acids Res., 11(23):8287 (1983)]. Other suitable promoters may be selected by one of skill in the art.

The minigene may also desirably contain nucleic acid sequences heterologous to the viral vector sequences including sequences providing signals required for efficient polyadenylation of the transcript (poly-A or pA) and introns with functional splice donor and acceptor sites. A common poly-A sequence which is employed in the exemplary vectors of this invention is that derived from the papovavirus SV-40. The poly-A sequence generally is inserted in the minigene following the transgene sequences and before the viral vector sequences. A common intron sequence is also derived from SV-40, and is referred to as the SV-40 T intron sequence. A minigene of the present invention may also contain such an intron, desirably located between the promoter/enhancer sequence and the transgene. Selection of these and other common vector elements are conventional [see, e.g., Sambrook et al, "Molecular Cloning. A Laboratory Manual.", 2d ed., Cold Spring Harbor Laboratory, New York (1989) and references cited therein] and many such sequences are available from commercial and industrial sources as well as from Genbank.

As stated above, the minigene is located in the site of any selected deletion in the viral vector. See Example 1 below.

B. Construction of The Viral Plasmid Vector
Although a number of viral vectors have been suggested for gene therapy, the most desirable vector for this purpose is a recombinant adenoviral vector or adeno-associated vector. Adenovirus vectors as described below are preferred because they can be purified in large quantities and highly concentrated, and the virus can transduce genes into non-dividing cells.

However, it is within the skill of the art for other adenovirus, or even retrovirus, vaccinia or other virus vectors to be similarly constructed.

Adenoviruses are eukaryotic DNA viruses

5 that can be modified to efficiently deliver a therapeutic or reporter transgene to a variety of cell types. Human adenoviruses comprise a linear, approximately 36 kb double-stranded DNA genome, which is divided into 100 map units (m.u.), each of which is 360 bp in length. The DNA
10 contains short inverted terminal repeats (ITR) at each end of the genome that are required for viral DNA replication. The gene products are organized into early (E1 through E4) and late (L1 through L5) regions, based on expression before or after the initiation of viral DNA
15 synthesis [see, e.g., Horwitz, Virology, 2d edit., ed. B. N. Fields, Raven Press, Ltd., New York (1990)]. The general adenoviruses types 2 and 5 (Ad2 and Ad5, respectively), are not associated with human malignancies.

20 Suitable adenovirus vectors useful in gene therapy are well known [see, e.g., M. S. Horwitz et al, "Adenoviridae and Their Replication", Virology, second edition, pp. 1712, ed. B. N. Fields et al, Raven Press Ltd., New York (1990); M. Rosenfeld et al, Cell, 68:143-
25 155 (1992); J. F. Engelhardt et al, Human Genet. Ther., 4:759-769 (1993); Y. Yang et al, Nature Genet., 7:362-269 (1994); J. Wilson, Nature, 365:691-692 (Oct. 1993); B. J. Carter, in "Handbook of Parvoviruses", ed. P. Tijsser, CRC Press, pp. 155-168 (1990). The selection of the
30 adenovirus type is not anticipated to limit the following invention.

Adenovirus vectors useful in this invention may include the DNA sequences of a number of adenovirus types. The adenovirus sequences useful in the
35 vectors described herein may be obtained from any known

adenovirus type, including the presently identified 41 human types [see, e.g., Horwitz, cited above]. The sequence of a strain of adenovirus type 5 may be readily obtained from Genbank Accession No. M73260. Similarly, 5 adenoviruses known to infect other animals may also be employed in the vector constructs of this invention. A variety of adenovirus strains are available from the American Type Culture Collection, Rockville, Maryland, or available by request from a variety of commercial and 10 institutional sources.

Adenovirus vectors useful in this invention include recombinant, defective adenoviruses, optionally bearing other mutations, e.g., temperature-sensitive mutations, deletions and hybrid vectors formed 15 with adenovirus/adeno-associated virus sequences. Suitable vectors are described in the published literature [see, for example, Kozarsky I and II, cited above, and references cited therein, U. S. Patent No. 5,240,846 and the co-pending applications incorporated 20 herein by reference below.

Useful adenovirus vectors for delivery of the VLDLR gene to the liver, minimal adenovirus nucleic acid sequences may be used to make a vector, in which case the use of a helper virus to produce a hybrid virus 25 particle is required. Alternatively, only selected deletions of one or more adenovirus genes may be employed to construct a viral vector. Deleted gene products can be supplied by using a selected packaging cell line which supplies the missing gene product.

30 1. Recombinant Minimal Adenovirus

Desirable adenovirus (Ad) vectors useful in the present invention are described in detail in co-pending, co-owned U.S. Patent Application Serial No. 08/331,381, which is incorporated by reference herein 35 for the purpose of describing these vectors.

Briefly summarized, the minimal Ad virus is a viral particle containing only the adenovirus cis-elements necessary for replication and virion encapsidation, but otherwise deleted of all adenovirus genes. That is, the vector contains only the cis-acting 5' and 3' inverted terminal repeat (ITR) sequences of an adenovirus (which function as origins of replication) and the native 5' packaging/enhancer domain, that contains sequences necessary for packaging linear Ad genomes and enhancer elements for the E1 promoter. This left terminal (5') sequence of the Ad5 genome spans bp 1 to about 360 of the conventional published Ad5 adenovirus genome, also referred to as map units 0-1 of the viral genome, and generally is from about 353 to about 360 nucleotides in length. This sequence includes the 5'ITR (bp 1 to about 103 of the adenovirus genome); and the packaging/enhancer domain (bp about 194 to about 358 of the adenovirus genome). The minimal 3' adenovirus sequences of the adenovirus vector may include the right terminal (3') ITR sequence of the adenoviral genome spanning about bp 35,353 to the end of the adenovirus genome, or map units ~98.4-100. This sequence is generally about 580 nucleotide in length. Between such sequences, a VLDLR minigene, as described above, is inserted.

Production of an infectious particle from this minimal Ad viral vector involves the assistance of a helper virus, as discussed below. A second type of minimal vector also disclosed in the above-incorporated reference places the 5' Ad terminal sequence in a head-to-tail arrangement relative to the 3' terminal sequence. The minimal Ad vector co-infected with a helper virus and/or a packaging cell line provides all of the viral gene products necessary to produce an infective recombinant viral particle containing the VLDLR minigene.

Alternatively, this vector can contain additional adenovirus gene sequences, which then are not required to be supplied by a helper virus.

2. Other Defective Adenoviruses

5 Recombinant, replication-deficient adenoviruses useful for gene therapy of this invention may be characterized by containing more than the minimal adenovirus sequences defined above. These other Ad vectors can be characterized by deletions of various
10 portions of gene regions of the virus, and infectious virus particles formed by the optional use of helper viruses and/or packaging cell lines. Suitable defective adenoviruses are described in more detail in Kozarsky and Wilson, Curr. Opin. Genet. Devel., 3:499-503 (1993);
15 Kozarsky I and II, cited above, and references cited therein, all incorporated herein by reference.

As one example, suitable vectors may be formed by deleting all or a sufficient portion of the adenoviral early immediate early gene E1a (which spans mu 20 1.3 to 4.5) and delayed early gene E1b (which spans mu 4.6 to 11.2) so as to eliminate their normal biological functions. These replication-defective E1-deleted viruses are capable of replicating and producing infectious virus when grown on an adenovirus-transformed, complementation human embryonic kidney cell line, the 293 cell [ATCC CRL1573], containing functional adenovirus E1a and E1b genes which provide the corresponding gene products in trans. The resulting virus is capable of infecting many cell types and can express a transgene 25 (i.e., VLDLR gene), but cannot replicate in most cells that do not carry the E1 region DNA unless the cell is infected at a very high multiplicity of infection. Extensive experience in animals indicates that E1-deleted vectors are not particularly desirable for gene therapy
30

because low levels of viral proteins are expressed which elicit destructive cellular immune responses.

As a preferred example, all or a portion of the adenovirus delayed early gene E3 (which spans mu 76.6 to 86.2) may be eliminated from the adenovirus sequence which forms a part of the hybrid construct. The function of E3 is irrelevant to the function and production of the recombinant virus particle. For example, Ad vectors may be constructed with a therapeutic minigene inserted into the E1-deleted region of the known mutant Ad5 sub360 backbone [J. Logan et al, Proc. Natl. Acad. Sci. USA, 81:3655-3659 (1984)]; or the Ad5 mutant dl7001 backbone [Dr. William Wold, Washington University, St. Louis]. Both mutant viruses also contain a deletion in the E3 region of the adenoviral genome; in sub360, at 78.5 to 84.3 mu, and in dl7001, at 78.4 to 86 mu. The life cycle of both sub360 and dl7001 display wild type characteristics.

More preferred adenovirus vectors may be constructed having a deletion of the E1 gene, at least a portion of the E3 region, and an additional deletion within adenovirus genes other than E1 and E3 to accommodate the VLDLR minigene and/or other mutations which result in reduced expression of adenoviral protein and/or reduced viral replication. For example, all or a portion of the adenovirus delayed early gene E2a (which spans mu 67.9 to 61.5) may be eliminated from the adenovirus vector. It is also anticipated that portions of the other delayed early genes E2b (which spans mu 29 to 14.2) and E4 (which spans mu 96.8 to 91.3) may also be eliminated from the adenovirus vector.

Deletions may also be made in any of the late genes L1 through L5, which span mu 16.45 to 99 of the adenovirus genome. Similarly, deletions may be useful in the intermediate genes IX (which maps between

mu 9.8 and 11.2) and IVa₂ (which maps between 16.1 to 11.1). Other useful deletions may also be made in the other structural or non-structural adenovirus genes.

An adenovirus sequence for use in the present invention may contain deletions of E1 only. Alternatively, deletions of entire genes or portions effective to destroy their biological activity may be used in any combination. For example, in one exemplary vector, the adenovirus sequence may contain deletions of the E1 genes and the E3 gene, or of the E1, E2a and E3 genes, or of the E1 and E4 genes, or of E1, E2a and E4 genes, with or without deletion of E3, and so on.

Vectors may also contain additional mutations in genes necessary for viral replication. Adenovirus vectors may contain a mutation which produces temperature-sensitive (ts) viruses. Among such mutations include the incorporation of the missense temperature-sensitive mutation in the E2a region found in the Ad5 H5ts125 strain [P. Vander Vliet et al, J. Virol., 15:348-354 (1975)] at 62.5 mu. A single amino acid substitution (62.5 mu) at the carboxy end of the 72 kd protein (DBP) produced from the E2a gene in this strain produces a protein product which is a single-stranded DNA binding protein and is involved in the replication of adenoviral genomic DNA. At permissive temperatures (approximately 32°C) the ts strain is capable of full life cycle growth on HeLa cells, while at non-permissive temperatures (approximately 38°C), no replication of adenoviral DNA is seen. In addition, at non-permissive temperatures, decreased immunoreactive 72 kd protein is seen in HeLa cells.

Exemplary vectors for use in this invention, for example, may be obtained by combining

fragments from three independent DNA constructs, including sub360 or d17001, H5ts125, and a cDNA plasmid with E1a sequences placed 5' to a therapeutic minigene. This type of vector is described, for example, by J. F.

5 Engelhardt et al, Proc. Natl. Acad. Sci. USA, 91:6196-6200 (June 1994); Y. Yang et al, Nature Genet., 7: 362-369 (July, 1994) and references cited therein, all references incorporated herein by reference. Due to the mutations in the vector, there is reduced viral

10 replication, reduction in expressed protein and an increase in the persistence of transgene expression. Other preferred adenovirus vectors contain the H5ts125 mutation in addition to E3 deletions of sub360 and d17001. The minigene containing VLDLR as the transgene

15 may be inserted into any deleted region of the selected Ad virus.

An exemplary Ad virus vector used to demonstrate this invention is the defective adenovirus vector H5.010CMVVLDLR, which contains adenovirus

20 sequences Ad m.u. 0-1, followed by a VLDLR minigene, and the sequence Ad m.u.9 to 100 with small deletions in E3. See Fig. 3, described above. The recombinant adenovirus was fully deleted of E1a, E1b and partially deleted of E3. This recombinant virus vector is described in detail

25 in Example 1.

3. Ad/AAV Hybrid Vectors

Another preferred vector is a hybrid Ad/AAV vector, which is the subject of co-owned, co-pending U.S. Patent Application Ser. No. 08/331,384,

30 which is incorporated by reference herein.

At a minimum, the adenovirus nucleic acid sequences employed in the hybrid vector of this invention are the minimal adenovirus genomic sequences required for packaging adenoviral genomic DNA into a preformed capsid head, as described above. The entire

adenovirus 5' sequence containing the 5'ITR and packaging/enhancer region can be employed as the 5' adenovirus sequence in the hybrid vector. The 3' adenovirus sequences of the vector include the right 5 terminal (3') ITR sequence of the adenoviral genome discussed above. Some modifications to these sequences which do not adversely affect their biological function may be acceptable.

Also part of the hybrid vectors of 10 this invention are sequences of an adeno-associated virus. The AAV sequences useful in the hybrid vector are the viral sequences from which the rep and cap polypeptide encoding sequences are deleted. More specifically, the AAV sequences employed are the cis- 15 acting 5' and 3' inverted terminal repeat (ITR) sequences [See, e.g., B. J. Carter, cited above]. The AAV ITR sequences are about 143 bp in length. Substantially the entire sequences encoding the ITRs are used in the vectors, although some degree of minor modification of 20 these sequences is expected to be permissible for this use. The ability to modify these ITR sequences is within the skill of the art. See, e.g., Sambrook et al, cited above.

In the Ad/AAV hybrid vector 25 construct, the AAV sequences are flanked by the adenovirus sequences discussed above. The 5' and 3' AAV ITR sequences themselves flank a VLDLR minigene sequence as described above. Thus, the sequence formed by the VLDLR minigene and flanking 5' and 3' AAV sequences may 30 be inserted at any deletion site in the adenovirus sequences of the vector. For example, the AAV sequences are desirably inserted at the site of deleted E1a/E1b genes of the adenovirus, i.e., after map unit 1. Alternatively, the AAV sequences may be inserted at an E3 35 deletion, E2a deletion, and so on. If only the

adenovirus 5' ITR/packaging sequences and 3' ITR sequences are used in the vector, the AAV sequences are inserted between them.

As described above for the minimum

- 5 adenovirus sequences, those gene sequences not present in the adenovirus portion of the hybrid vector must be supplied by either a packaging cell line and/or a helper adenovirus to generate the recombinant hybrid viral particle. Uptake of this hybrid virus by the cell is
- 10 caused by the infective ability contributed to the vector by the adenovirus and AAV sequences. Once the virus or virus conjugate is taken up by a cell, the AAV ITR flanked transgene must be rescued from the parental adenovirus backbone. Rescue of the transgene is
- 15 dependent upon supplying the infected cell with an AAV rep gene.

The AAV rep gene can be supplied to the hybrid virus by several methods described in the above-incorporated application. One embodiment for

- 20 providing rep proteins in *trans* is by transfecting into the target monolayer of cells previously infected with the hybrid vector, a liposome enveloped plasmid containing the genes encoding the AAV rep 78 kDa and 52 kDa proteins under the control of the AAV P5 promoter.
- 25 More preferably for *in vivo* use, the AAV rep gene may also be delivered as part of the hybrid virus. One embodiment of this single particle concept is supplied by a polycation conjugate of hybrid virus. Infection of this modified virus conjugate is accomplished in the same
- 30 manner and with regard to the same target cells as identified above. However, the polylysine conjugate of the hybrid virus onto which was directly complexed a plasmid that encoded the rep 78 and 52 proteins, combines all of the functional components into a single particle
- 35 structure. Thus, the hybrid virus conjugate permits

delivery of a single particle to the cell, which is considerably more desirable for therapeutic use. In another embodiment, the hybrid virus is modified by cloning the *rep* cDNA directly into the adenovirus genome portion of the hybrid vector.

5 These and additional aspects of this hybrid vector are provided by the above-incorporated by reference application.

10 **C. Production of the Recombinant Viral Particle**

15 **1. Helper Viruses/Packaging Cell Lines**

Depending upon the adenovirus gene content of the plasmid vectors employed to carry the VLDLR minigene, a packaging cell line or a helper adenovirus or both may be necessary to provide sufficient adenovirus gene sequences necessary to produce an infective recombinant viral particle containing the VLDLR minigene.

20 Useful helper viruses contain selected adenovirus gene sequences not present in the adenovirus vector construct or expressed by the cell line in which the vector is transfected. A preferred helper virus is desirably replication defective and contains a variety of adenovirus genes in addition to the modified sequences described above. In this setting, the helper virus is desirably used in combination with a packaging cell line that stably expresses adenovirus genes. Helper viruses may also be formed into poly-cation conjugates as described in Wu et al, J. Biol. Chem., 264:16985-16987 (1989); K. J. Fisher and J. M. Wilson, Biochem. J., 299:49 (April 1, 1994), and in U. S. Patent Application Serial No. 08/331,381, incorporated by reference herein.

30 Helper virus may optionally contain a second reporter minigene. A number of such reporter

genes are known to the art. The presence of a reporter gene on the helper virus which is different from the transgene on the adenovirus vector allows both the Ad vector and the helper virus to be independently

5 monitored. This second reporter is used to enable separation between the resulting recombinant virus and the helper virus upon purification. The construction of desirable helper cells is within the skill of the art.

As one example, if the cell line
10 employed to produce the viral vector is not a packaging cell line, and the vector contains only the minimum adenovirus sequences identified above, the helper virus may be a wild type Ad vector supplying the necessary adenovirus early genes E1, E2a, E4 and all remaining
15 late, intermediate, structural and non-structural genes of the adenovirus genome. However, if, in this situation, the packaging cell line is 293, which supplies the E1 proteins, the helper cell line need not contain the E1 gene.

20 In another embodiment, if the adenovirus vector construct is replication defective (no E1 gene and optionally no E3 gene) and the 293 cell line is employed, no helper virus is necessary for production of the hybrid virus. E3 may be eliminated from the
25 helper virus because this gene product is not necessary for the formation of a functioning virus particle.

Preferably, to facilitate purification and reduce contamination of the viral vector particle with the helper virus, it is useful to modify
30 the helper virus' native adenoviral gene sequences which direct efficient packaging, so as to substantially disable or "cripple" the packaging function of the helper virus or its ability to replicate.

A desirable "crippled" adenovirus is
35 modified in its 5' ITR packaging/enhancer domain, which

normally contains at least seven distinct yet functionally redundant sequences necessary for efficient packaging of replicated linear adenovirus genomes ("PAC" sequences). Within a stretch of nucleotide sequence from 5 bp 194-358 of the Ad5 genome, five of these PAC sequences are localized: PAC I or its complement at bp 241-248 [SEQ ID NO: 4], PAC II or its complement at bp 262-269 [SEQ ID NO: 5], PAC III or its complement at bp 304-311 [SEQ ID NO: 6], PAC IV or its complement at bp 314-321 [SEQ ID NO: 7], and PAC V or its complement at bp 339-346 [SEQ ID NO: 8].

Mutations or deletions may be made to one or more of these PAC sequences in an adenovirus helper virus to generate desirable crippled helper viruses. Modifications of this domain may include 5' adenovirus sequences which contain less than all five of the native adenovirus PAC sequences, including deletions of contiguous or non-contiguous PAC sequences. An alternative modification may be the replacement of one or 10 more of the native PAC sequences with one or more repeats of a consensus sequence containing the most frequently used nucleotides of the five native PAC sequences. Alternatively, this adenovirus region may be modified by deliberately inserted mutations which disrupt one or more 15 of the native PAC sequences. One of skill in the art may further manipulate the PAC sequences to similarly achieve 20 the effect of reducing the helper virus packaging efficiency to a desired level.

It should be noted that one of skill 25 in the art may design other helper viruses or develop other packaging cell lines to complement the adenovirus deletions in the vector construct and enable production of the recombinant virus particle, given this information. Therefore, the use or description of any

particular helper virus or packaging cell line is not limiting.

In the presence of other packaging cell lines which are capable of supplying adenoviral proteins in addition to the E1, the helper virus may accordingly be deleted of the genes encoding these adenoviral proteins. Such additionally deleted helper viruses also desirably contain crippling modifications as described above.

10 Poly-cation helper virus conjugates, which may be associated with a plasmid containing other adenoviral genes, which are not present in the helper virus may also be useful. The helper viruses described above may be further modified by resort to adenovirus-polylysine conjugate technology. See, e.g., Wu et al., cited above; and K. J. Fisher and J. M. Wilson, cited above.

15 Using this technology, a helper virus containing preferably the late adenoviral genes is modified by the addition of a poly-cation sequence distributed around the capsid of the helper virus. Preferably, the poly-cation is poly-lysine, which attaches around the negatively-charged vector to form an external positive charge. A plasmid is then designed to express those adenoviral genes not present in the helper virus, e.g., the E1, E2 and/or E4 genes. The plasmid associates to the helper virus-conjugate through the charges on the poly-lysine sequence. This conjugate permits additional adenovirus genes to be removed from the helper virus and be present on a plasmid which does not become incorporated into the virus during production of the recombinant viral vector. Thus, the impact of contamination is considerably lessened.

2. Assembly of Viral Particle and
Infection of a Cell Line

Assembly of the selected DNA sequences of the adenovirus, the AAV and the reporter genes or therapeutic genes and other vector elements into the hybrid vector and the use of the hybrid vector to produce a hybrid viral particle utilize conventional techniques. Such techniques include conventional cloning techniques of cDNA such as those described in texts [Sambrook et al, cited above], use of overlapping oligonucleotide sequences of the adenovirus and AAV genomes, polymerase chain reaction, and any suitable method which provides the desired nucleotide sequence. Standard transfection and co-transfection techniques are employed, e.g., CaPO₄ transfection techniques using the complementation 293 cell line. Other conventional methods employed include homologous recombination of the viral genomes, plaquing of viruses in agar overlay, methods of measuring signal generation, and the like.

For example, following the construction and assembly of the desired minigene-containing plasmid vector, the vector is infected *in vitro* in the presence of an optional helper virus and/or a packaging cell line. Homologous recombination occurs between the helper and the vector, which permits the adenovirus-transgene sequences in the vector to be replicated and packaged into virion capsids, resulting in the recombinant vector viral particles. The current method for producing such virus particles is transfection-based. Briefly, helper virus is used to infect cells, such as the packaging cell line human HEK 293, which are then subsequently transfected with an adenovirus plasmid vector containing a VLDLR transgene by conventional methods. About 30 or more hours post-transfection, the cells are harvested, an extract

prepared and the recombinant virus vector containing the VLDLR transgene is purified by buoyant density ultracentrifugation in a CsCl gradient.

The yield of transducing viral

5 particles is largely dependent on the number of cells that are transfected with the plasmid, making it desirable to use a transfection protocol with high efficiency. One such method involves use of a poly-L-lysinylated helper adenovirus as described above. A
10 plasmid containing the VLDLR minigene is then complexed directly to the positively charged helper virus capsid, resulting in the formation of a single transfection particle containing the plasmid vector and the helper functions of the helper virus.

15 **II. Use of the Recombinant Virus Vectors in Gene Therapy**

The resulting recombinant adenoviral vector containing the VLDLR minigene produced by cooperation of the adenovirus vector and helper virus or adenoviral vector and packaging cell line, as described above, thus
20 provides an efficient gene transfer vehicle which can deliver the VLDLR gene to a patient *in vivo* or *ex vivo* and provide for integration of the gene into a liver cell.

The above-described recombinant vectors are
25 administered to humans in a conventional manner for gene therapy and serve as an alternative or supplemental gene therapy for LDL receptor deficiencies or other lipoprotein metabolic disorders. A viral vector bearing the VLDLR gene may be administered to a patient,
30 preferably suspended in a biologically compatible solution or pharmaceutically acceptable delivery vehicle. A suitable vehicle includes sterile saline. Other aqueous and non-aqueous isotonic sterile injection solutions and aqueous and non-aqueous sterile suspensions

known to be pharmaceutically acceptable carriers and well known to those of skill in the art may be employed for this purpose.

The viral vectors are administered in sufficient amounts to transfect the liver cells and provide sufficient levels of transfer and expression of the VLDLR gene to provide a therapeutic benefit without undue adverse or with medically acceptable physiological effects which can be determined by those skilled in the medical arts. Conventional and pharmaceutically acceptable routes of administration include direct delivery to the liver, intranasal, intravenous, intramuscular, subcutaneous, intradermal, oral and other parental routes of administration. Routes of administration may be combined, if desired.

Dosages of the viral vector will depend primarily on factors such as the condition being treated, the age, weight and health of the patient, and may thus vary among patients. For example, a therapeutically effective human dosage of the viral vector is generally in the range of from about 20 to about 100 ml of saline solution containing concentrations of from about 1×10^9 to 1×10^{11} pfu/ml virus vector. A preferred human dosage is estimated to be about 50 ml saline solution at 2×10^{10} pfu/ml. The dosage will be adjusted to balance the therapeutic benefit against any adverse side effects. The levels of expression of the VLDLR gene can be monitored to determine the frequency of dosage administration.

An optional method step involves the co-administration to the patient, either concurrently with, or before or after administration of the viral vector, of a suitable amount of an immune modulator, which is preferably short-acting. The selected immune modulator is defined herein as an agent capable of inhibiting the

formation of neutralizing antibodies directed against products of the recombinant vector of this invention and/or capable of inhibiting cytolytic T lymphocyte (CTL) elimination of the vector containing cells. The immune modulator may interfere with the interactions between the T helper subsets (T_{H1} or T_{H2}) and B cells to inhibit neutralizing antibody formation. Alternatively, the immune modulator may be selected to inhibit the interaction between T_{H1} cells and CTLs to reduce the occurrence of CTL elimination of the vector. More specifically, the immune modulator desirably interferes with, or blocks, the function of the CD4 T cells.

Immune modulators for use in inhibiting neutralizing antibody formation may be selected based on the determination of the immunoglobulin subtype of any neutralizing antibody produced in response to the VLDLR-containing adenovirus vector. For example, if the neutralizing antibody is a T_{H2} mediated antibody, such as IgA, the immune modulator desirably suppresses or prevents the interaction of T_{H2} with B cells. Alternatively, if the induced neutralizing antibody is a T_{H1} mediated antibody, such as IgG_{2A}, the immune modulator desirably suppresses or prevents the interaction of T_{H1} with B cells.

The neutralizing antibody which develops in response to administration of a viral vector of this invention can be based on what vehicle is being used to deliver the vector and/or the location of delivery. For instance, administration of adenoviral vectors via the lungs generally induces production of IgA neutralizing antibody. Administration of adenoviral vectors via the blood generally induces IgG, neutralizing antibody. The determination of the neutralizing antibody is readily determined in trials of the selected viral vector in animal models. Where the reduction of CTL elimination of

the viral vectors is desired, the immune modulator is selected for its ability to suppress or block CD4⁺ T_{H1} cells to permit prolonged residence of the viral vector in vitro.

5 Selection of the immune modulator thus may be based upon the mechanism sought to be interrupted or blocked. The immune modulators may be soluble proteins or naturally occurring proteins, including cytokines, monoclonal antibodies. The immune modulators may be
10 conventional pharmaceuticals. The immune modulators identified herein may be used alone or in combination with one another. For example, cyclophosphamide and the more specific immune modulator anti-CD4 monoclonal antibody may be co-administered. In such a case,
15 cyclophosphamide serves as an agent to block T_{H1} activation and stabilized transgene expression beyond the period of transient immune blockade.

A suitable amount or dosage of the immune modulator will depend primarily on the amount of the recombinant vector bearing the VLDLR gene which is initially administered to the patient and the type of immune modulator selected. Other secondary factors such as the condition being treated, the age, weight, general health, and immune status of the patient, may also be
20 considered by a physician in determining the dosage of immune modulator to be delivered to the patient.
25

Generally, for example, a therapeutically effective human dosage of a cytokine immune modulator, e.g., IL-12 or γ -IFN, is generally in the range of from
30 about 0.5 μ g to about 5 mg per about 1×10^7 pfu/ml virus vector. Various dosages may be determined by one of skill in the art to balance the therapeutic benefit against any side effects.

A. Monoclonal Antibodies and Soluble Proteins

Preferably, the method of inhibiting an adverse immune response to the gene therapy vector involves non-specific inactivation of CD4⁺ cells.

- 5 Preferably, such blocking antibodies are "humanized" to prevent the recipient from mounting an immune response to the blocking antibody. A "humanized antibody" refers to an antibody having its complementarily determining regions (CDRs) and/or other portions of its light and/or
- 10 heavy variable domain framework regions derived from a non-human donor immunoglobulin, the remaining immunoglobulin-derived parts of the molecule being derived from one or more human immunoglobulins. Such antibodies can also include antibodies characterized by a
- 15 humanized heavy chain associated with a donor or acceptor unmodified light chain or a chimeric light chain, or vice versa. Such "humanization" may be accomplished by methods known to the art. See, for example, G.E. Mark and E. A. Padlan, "Chap. 4. Humanization of Monoclonal
- 20 Antibodies", The Handbook of Experimental Pharmacology, vol. 113, Springer-Verlag, New York (1994), pp. 105-133, which is incorporated by reference herein.

Other suitable antibodies include those that specifically inhibit or deplete CD4⁺ cells, such as

25 an antibody directed against cell surface CD4. Depletion of CD4⁺ cells has been shown by the inventors to inhibit the CTL elimination of the viral vector. Such modulatory agents include but are not limited to anti-T cell antibodies, such as anti-OKT3+ [see, e.g., US Patent No.

30 4,658,019; European Patent Application No. 501,233, published September 2, 1992]. See Example 2 below, which employs the commercially available antibody GK1.5 (ATCC Accession No. TIB207) to deplete CD4⁺ cells.

Alternatively, any agent that interferes with or blocks the interactions necessary for the activation of B cells by T_H cells, and thus the production of neutralizing antibodies, is useful as an immune modulator according to these methods. For example, B cell activation by T cells requires certain interactions to occur [F. H. Durie et al, Immunol. Today, 15(9):406-410 (1994)], such as the binding of CD40 ligand on the T helper cell to the CD40 antigen on the B cell, and the binding of the CD28 and/or CTLA4 ligands on the T cell to the B7 antigen on the B cell. Without both interactions, the B cell cannot be activated to induce production of the neutralizing antibody.

The CD40 ligand (CD40L)-CD40 interaction is a desirable point to block the immune response to gene therapy vectors because of its broad activity in both T helper cell activation and function as well as the absence of redundancy in its signaling pathway. A currently preferred method of the present invention thus involves transiently blocking the interaction of CD40L with CD40 at the time of adenoviral vector administration. This can be accomplished by treating with an agent which blocks the CD40 ligand on the T_H cell and interferes with the normal binding of CD40 ligand on the T helper cell with the CD40 antigen on the B cell. Blocking CD40L-CD40 interaction prevents the activation of the T helper cells that contributes to problems with transgene stability and readministration.

Thus, an antibody to CD40 ligand (anti-CD40L) [available from Bristol-Myers Squibb Co; see, e.g., European patent application 555,880, published August 18, 1993] or a soluble CD40 molecule can be a selected immune modulator in this method.

Alternatively, an agent which blocks the CD28 and/or CTLA4 ligands present on T helper cells interferes with the normal binding of those ligands with the antigen B7 on the B cell. Thus, a soluble form of B7 or an antibody to CD28 or CTLA4, e.g., CTLA4-Ig [available from Bristol-Myers Squibb Co; see, e.g., European patent application 606,217, published July 20, 1994] can be the selected immune modulator in the method of this invention. This method has greater advantages than the below-described cytokine administration to prevent T_{H2} activation, because it addresses both cellular and humoral immune responses to foreign antigens.

B. Cytokines

Still other immune modulators which inhibit the T_{H2} cell function may be employed in this invention.

Thus, in one embodiment, an immune modulator which selectively inhibits the function of the T_{H1} subset of CD4 $^{+}$ T helper cells may be administered at the time of primary administration of the viral vector. One such immune modulator is interleukin-4 (IL-4). IL-4 enhances antigen specific activity of T_{H2} cells at the expense of the T_{H1} cell function [see, e.g., Yokota et al, Proc. Natl. Acad. Sci., USA, 83:5894-5898 (1986); United States Patent No. 5,017,691]. It is envisioned that other immune modulators that can inhibit T_{H1} cell function will also be useful in the methods of this invention.

In another embodiment, the immune modulator can be a cytokine that prevents the activation of the T_{H2} subset of T helper cells. The success of this method depends on the relative contribution that T_{H2} dependent Ig isotypes play in virus neutralization, the profile of which may be affected by strain, the species

of animal as well as the mode of virus delivery and target organ.

A desirable immune modulator which selectively inhibits the CD4⁺ T cell subset T_{H2} function at the time of primary administration of the viral vector includes interleukin-12 (IL-12). IL-12 enhances antigen specific activity of T_{H1} cells at the expense of T_{H2} cell function [see, e.g., European Patent Application No. 441,900; P. Scott, Science, 260:496-497 (1993); R. Manetti et al, J. Exp. Med., 177:1199 (1993); A. D'Andrea et al, J. Exp. Med., 176:1387 (1992)]. IL-12 for use in this method is preferably in protein form. Human IL-12 may be recombinantly produced using known techniques or may be obtained commercially. Alternatively, it may be engineered into a viral vector (which optionally may be the same as that used to express the transgene) and expressed in a target cell *in vivo* or *ex vivo*.

T_{H2} specific ablation with IL-12 is particularly effective in lung-directed gene therapies where IgA is the primary source of neutralizing antibody. In liver-directed gene therapy, both T_{H1} and T_{H2} cells contribute to the production of virus specific antibodies. However, the total amount of neutralizing antibody can be diminished with IL-12.

Another selected immune modulator which performs a similar function is gamma interferon (IFN- γ) [S. C. Morris et al, J. Immunol., 152:1047-1056 (1994); F. P. Heinzel et al, J. Exp. Med., 177:1505 (1993)]. IFN- γ is believed to mediate many of the biological effects of IL-12 via secretion of activated macrophages and T helper cells. IFN- γ also partially inhibits IL-4 stimulated activation of T_{H2}. IFN- γ may also be obtained from a variety of commercial sources.

Alternatively, it may be engineered into a viral vector and expressed in a target cell *in vivo* or *ex vivo* using known genetic engineering techniques.

Preferably, such cytokine immune

- 5 modulators are in the form of human recombinant proteins. These proteins may be produced by methods extant in the art. Active peptides, fragments, subunits or analogs of the known immune modulators described herein, such as IL-12 or gamma interferon, which share the T_{H2} inhibitory
10 function of these proteins, will also be useful in this method when the neutralizing antibodies are T_{H2} mediated.

C. Other Pharmaceuticals

- Other immune modulators or agents that non-specifically inhibit immune function, i.e.,
15 cyclosporin A or cyclophosphamide, may also be used in the methods of the invention. For example, a short course of cyclophosphamide has been demonstrated to successfully interrupt both CD4 and CD8 T helper cell activation to adenovirus capsid protein at the time of
20 virus delivery to the liver. As a result, transgene expression was prolonged and, at higher doses, formation of neutralizing antibody was prevented, allowing successful vector readministration. In the lung, cyclophosphamide prevented formation of neutralizing
25 antibodies at all doses and stabilized transgene expression at high dose.

D. Administration of Immune Modulator

- The optional administration of the selected immune modulator may be repeated during the
30 treatment with the recombinant adenovirus vector carrying the human VLDLR gene, during the period of time that the VLDLR gene is expressed (as monitored by e.g., LDL levels), or with every booster of the recombinant vector.

Thus, the compositions and methods of this invention provide a desirable treatment for defects in LDL metabolism, by providing stable expression of the VLDLR gene in human hepatocytes, and the ability to re-administer the vector as desired without incurring an undesired immune response by the patient.

The following examples illustrate the construction and testing of the viral vectors and VLDL receptor gene inserts of the present invention and the use thereof in the treatment of metabolic disorders. An exemplary recombinant adenovirus encoding the human VLDL receptor was constructed as described in Example 1 below. These examples are illustrative only, and do not limit the scope of the present invention.

15 Example 1 - Construction and Purification of H5.010CMVVLDLR

The cDNA for the human very low density lipoprotein (VLDL) receptor [M. E. Gafvels et al, cited above; SEQ ID NO: 1] was inserted into the polylinker region of plasmid pRc/CMV (obtained from Invitrogen Corp.). The resulting plasmid, pRc/CMVVLDLR, was digested with the restriction enzymes SnaBI and NotI and the 4 kb fragment containing the cytomegalovirus (CMV) immediate-early promoter and VLDL receptor cDNA was isolated.

The plasmid pAd.CMVlacZ [Kozarsky II, cited above] was digested with SnaBI and NotI to remove the CMV promoter and lacZ cDNA and the 5.6 kb backbone was isolated. The two fragments were ligated to generate pAd.CMVVLDLR (Figs. 2 and 9; SEQ ID NO: 3). pAd.CMVVLDLR was linearized with NheI and co-transfected into 293 cells with sub360 DNA (derived from adenovirus type 5) which had been digested with XbaI and ClaI as previously described [K. F. Kozarsky I and II cited above].

The resulting recombinant adenovirus, designated H5.010CMVVL_DLR, contains the sequence from about nucleotide 12 to about 4390 of pAd.CMVVL_DLR and Ad.5 map units 9-100 with a small deletion in the E3 gene (see GenBank Accession No. M73260 and discussion of Fig. 3). This recombinant adenovirus was isolated following two rounds of plaque purification. H5.010CMVVL_DLR was grown on 293 cells and purified by two rounds of cesium chloride density centrifugation as previously described [K. F. Kozarsky I and II cited above]. Cesium chloride was removed by passing the virus over a BioRad 1ODG desalting column equilibrated with phosphate-buffered saline.

For rabbit experiments, virus was used freshly purified; for mouse experiments, virus was either used fresh, or after column purification glycerol was added to a final concentration of 10% (v/v), and virus was stored at -70°C until use.

As described in the following examples, this recombinant adenovirus vector was introduced into the livers of WHHL rabbits and into the livers of LDL receptor knockout mice to determine the *in vivo* function of the VLDL receptor, and to determine its usefulness as an alternative or supplemental gene therapy for LDL receptor deficiency.

Example 2 - Other Recombinant Adenoviruses

H5.010CMVlacZ, encoding the lacZ gene under the control of the CMV enhancer/promoter, and H5.010CBhLD_LLR, encoding the human low density lipoprotein (LDL) receptor cDNA under the control of the CMV-enhanced chicken β -actin promoter, were prepared as previously described [K. F. Kozarsky I and II, cited above].

Example 3 - Effects of Hepatic Expression of the VLDL Receptor in the WHHL Rabbit

H5.010CMVVLDLR or H5.010CMVlacZ (encoding β -galactosidase), obtained as described in Examples 1 and 5, was infused intravenously into WHHL rabbits [Camm Research] as follows. Rabbits were infused with 7.5×10^{12} particles of either recombinant adenovirus through a marginal ear vein on day 0. In addition, two New Zealand White (NZW) rabbits [Hazleton, Inc.] were infused with 10 each virus and sacrificed on day 5 post-infusion to document the extent of gene transfer in the liver.

Rabbits were maintained in a 12 hour light/dark cycle on a diet of Purina laboratory chow, delivered each day at approximately 11:00 am. Venous samples were 15 obtained through a marginal ear vein at approximately 10:00 am on the days indicated.

A. Plasma Analyses

Plasma samples were analyzed for total cholesterol using the Cholesterol HP kit and Precise 20 standards (Boehringer Mannheim). Briefly, FPLC analysis was performed on 50 μ l of plasma from individual mice adjusted to a volume of 250 μ l in FPLC column buffer (1 mM EDTA, 154 mM NaCl, pH 8.0). Diluted samples (200 μ l) were loaded onto two Superose 6 columns (Pharmacia) in 25 series at a flow rate of 0.4 ml/min; and 1 ml fractions were collected. Cholesterol content was analyzed in a microplate assay on 100 μ l samples. 100 μ l of a freshly prepared solution containing 50 mM PIPES, pH 6.9, 7.8 g/L HDCBS, 0.51 g/L 4-AAT, 1.27 g/L cholic acid, 0.245% 30 Triton X-100, 7.31 g/L KCl and supplemented with 1.22 U/ml cholesterol oxidase, 7.64 U/ml cholesterol esterase, and 245 U/ml peroxidase was added to samples, incubated overnight at room temperature, and the O.D. at 490 nm was determined.

Plasma cholesterol levels were evaluated in each of the WHHL rabbits before and after receiving recombinant adenovirus. Fig. 4A shows that rabbits infused with H5.010CMVlacZ had no significant changes in 5 cholesterol levels. However, following infusion with H5.010CMVVLDLR, cholesterol levels dropped, with maximum decreases that ranged from 140 to 420 mg/dl (Fig. 4B). This demonstrated that expression of the VLDL receptor results in decreased cholesterol levels in LDL receptor-10 deficient rabbits.

B. Histochemical Analysis

Portions of liver were paraffin embedded, sectioned, and stained with hematoxylin and eosin. Some portions were fresh-frozen, sectioned, fixed in 15 glutaraldehyde, stained with X-gal and lightly counterstained with hematoxylin. Some fresh-frozen sections were fixed in methanol, and then stained with either a polyclonal anti- β -galactosidase antibody (5 prime-3 prime), a polyclonal anti-human LDL receptor 20 antibody, or with a polyclonal anti-VLDL receptor antibody, followed by a fluorescein isothiocyanate-conjugated anti-rabbit antibody (Jackson Immunoresearch) as previously described [K. F. Kozarsky I and II cited above]. Oil Red O staining was performed on fresh-frozen 25 sections fixed for 1 minute in 37% formaldehyde, then rinsed and stained in Oil Red O (3 parts 0.5% Oil Red O in isopropyl alcohol/2 parts water) for 10 minutes. Slides were counterstained in hematoxylin and mounted in aqueous solution.

30 Immunofluorescence analysis of the infused rabbits showed that approximately 50% of hepatocytes from the rabbit infused with H5.010CMVlacZ expressed β -galactosidase, liver tissue from the rabbit infused with H5.010CMVVLDLR had a slightly higher percentage of 35 hepatocytes expressing the VLDL receptor. In agreement

with Northern blot analysis showing little or no VLDL receptor mRNA expression [M. E. Gafvels et al, cited above], liver from the lacZ-infused rabbit showed no reactivity with the anti-VLDL receptor antibody.

5 Example 4 - Effects of Short-Term Hepatic Expression of the VLDL Receptor in LDL Receptor Knockout Mice

C57BL/6 mice and LDL receptor knockout mice (Jackson Labs) were infused intravenously with 0.5 or 1.0 x 10¹⁰ particles of recombinant adenovirus through the tail vein and cholesterol levels were monitored before and after infusion.

Specifically, three mice each were infused with either H5.010CMVlacZ, H5.010CMVVLDLR, or H5.010CBhLDLR (encoding the human LDL receptor cDNA). This last virus was included as a control to confirm published results [Kozarsky I and II cited above]. Plasma samples were obtained by retro-orbital bleeds using heparinized capillary tubes. The LDL receptor knockout mice were maintained upon a high cholesterol diet composed of Purina mouse chow supplemented with 1.25% cholesterol, 7.5% cocoa butter, 7.5% casein, and 0.5% cholate (1.25% cholesterol diet) for at least 3 weeks immediately following weaning before experiments were initiated. Mice were sacrificed on day 5 post-infusion.

25 Liver tissues were analyzed by immunofluorescence for transgene expression by the techniques described in Example 3, and plasma cholesterol levels were measured as similarly described. For lipoprotein fractionations, plasma from triplicate LDL receptor knockout mice were pooled, subjected to density ultracentrifugation, fractions were collected, and the cholesterol content was determined by conventional means.

Immunofluorescence analysis revealed moderate levels of β -galactosidase expression in H5.010CMVlacZ-infused mice, and higher levels of either human LDL receptor and VLDL receptor expression in H5.010CBhLDLR-5 and in H5.010CMVVLDLR-infused mice, respectively.

Cholesterol levels decreased slightly in the control, H5.010CMVlacZ-infused mice (Fig. 5), probably due to non-transgene-related effects of infusion of recombinant adenovirus, which can result in 10 hepatotoxicity in mice [Y. Yang et al, Proc. Natl. Acad. Sci., USA, 91:4407-4411 (May 1994)]. However, in contrast to the decrease observed in the control mice, cholesterol levels dropped significantly to 50% of pre-infusion values in the H5.010CBhLDLR-infused mice on day 15 5 post-infusion. Cholesterol levels in the H5.010CMVVLDLR-infused mice also decreased, to approximately 60% of pre-infusion levels. Further analysis of plasma lipoproteins showed that in the H5.010CBhLDLR-treated mice, LDL levels plummeted, with 20 additional decreases in IDL and VLDL fractions (Fig. 6). The H5.010CMVVLDLR-infused mice showed a larger decrease in the VLDL fraction with less of a decrease in LDL.

Taken together, these data indicate that hepatic expression of VLDL receptor results in increased 25 clearance of VLDL from the plasma, resulting in decreases in the amounts of lipoproteins for which VLDL is the precursor (i.e., IDL and LDL), and an overall drop in total plasma cholesterol.

Example 5 - Effects of Long-Term Hepatic Expression of
30 the VLDL Receptor in LDL Receptor Knockout Mice

In order to achieve cholesterol levels closer to those observed in both FH patients and WHHL rabbits, LDL receptor knockout mice (Jackson Labs) were maintained on a high cholesterol diet composed of Purina mouse chow

supplemented with 0.2% cholesterol, 10% coconut oil, and 0.05% cholate (0.2% cholesterol diet). Cholesterol levels in these mice ranged from 930 to 1550 mg/dl, whereas the mice on the 1.25% cholesterol (Example 4) 5 diet had levels of 1900 to 3100 mg/dl.

Virus was thawed immediately before use and diluted with PBS to a concentration of 1×10^{12} particles/ml. Three mice were each infused intravenously with 0.1 ml of virus containing 1×10^{11} particles of an 10 E1-deleted recombinant adenovirus encoding either β -galactosidase (H5.010CMVlacZ) or human LDL receptor (H5.010CBhLDLR), and serum lipids were followed over time. On the days indicated, mice were anesthetized with methoxyflurane and blood was collected into heparinized 15 capillary tubes by puncture of the retro-orbital venous plexus.

Immunofluorescence staining showed that most of the hepatocytes expressed the transgene product, either β -galactosidase, human LDL receptor, or VLDL receptor. 20 Hematoxylin and eosin staining of sections of liver revealed essentially normal morphology in the H5.010CMVlacZ-infused mouse. However, for both the H5.010CBhLDLR- and H5.010CMVLDLR-infused mice, hepatocytes appeared to have internal vacuoles. When 25 tissue was analyzed with Oil Red O staining, a stain for neutral lipids, liver from the receptor-infused animals clearly showed accumulation of large droplets of lipid when compared with the H5.010CMVlacZ-infused control. This suggested that short-term, high level expression of 30 the LDL receptor or VLDL receptor in these LDL receptor-deficient mice resulted in intracellular accumulation of lipids.

To confirm the biological activities of the transgene products, plasma cholesterol levels were 35 followed before and after recombinant adenovirus

administration. Fig. 7A shows that serum cholesterol levels in H5.010CMVlacZ-infused mice demonstrated a characteristic but not significant fluctuation over time, reflected in minor changes of all lipoprotein fractions (HDL, IDL/VLDL, and LDL). In contrast, mice infused with H5.010CBhLDLR have a large but transient decrease in cholesterol (see, Fig. 7B). Particularly, these mice demonstrated large plasma cholesterol decreases which lasted for approximately 2 weeks. Cholesterol levels decreased 3-fold (from 966 to 353 mg/dl) and 7-fold (from 1554 to 219 mg/dl) and returned to baseline by 3 weeks post-infusion. The decrease in serum cholesterol is reflected in coordinate diminution in serum LDL. This nonspecific effect of the adenovirus infection when immune modulators are not coordinately administered has been described previously and is likely due to changes in hepatic function that occur as a result of the associated inflammation. Mice infused with H5.010CMVVLDLR showed large decreases in plasma cholesterol which were similar in magnitude to those seen in the H5.010CBhLDLR-infused mice (Fig. 7C), with maximum decreases of more than 4-fold (from 1186 to 288 mg/dl and from 1453 to 299 mg/dl). Surprisingly, plasma cholesterol levels did not return to baseline by 3 weeks post-infusion. The change in plasma cholesterol levels in the H5.010CMVVLDLR-infused mice (Fig. 7A) were statistically significant ($p<0.05$) through 9 weeks following infusion (the current duration of the experiment).

Sera from individual mice was analyzed by FPLC to determine the effects of VLDL receptor expression on lipoprotein fractions. On day 3 post-infusion, VLDL and LDL fractions were undetectable; over time, the LDL fraction slowly recovered, although even at 10 weeks post-infusion, the LDL peak height was slightly lower than the HDL peak height. VLDL remained undetectable

although minor differences may escape detection because of limitations in the sensitivity of the cholesterol assay. The LDL peaks mirrored the total plasma cholesterol levels, and confirmed that the prolonged 5 lowering of plasma cholesterol was accompanied by sustained decreases in VLDL and LDL levels. These data suggest that expression of the VLDL receptor in the liver is an effective therapy for hypercholesterolemia.

At the same time of infusion of the LDL receptor knockout mice, normal C57Bl/6 mice were infused with each of the recombinant adenoviruses. These mice were sacrificed at various times post-infusion, and liver tissues were harvested for direct analysis of transgene expression using X-gal histochemistry to detect β -galactosidase expression and immunofluorescence performed to measure LDL receptor expression. Tissues harvested three days after infusion of virus demonstrated either expression of β -galactosidase or the human LDL receptor in at least 80% of hepatocytes.

In each experiment, the vector specific signal was substantially higher than that seen in animals before gene transfer or following infusion with identical quantities of an adenovirus expressing an irrelevant gene. For both lacZ and LDL receptor, transgene expression diminished to undetectable levels by day 21 and was associated with the development of a self limited mononuclear infiltrate in liver that peaked at day 10. The infiltrate consisted of portal as well as lobular inflammation, accompanied by the presence of apoptic 25 bodies. The extent of pathology was indistinguishable between the lacZ and LDL receptor infused mice. The time course of LDL receptor expression is consistent with the initial large decline in plasma cholesterol and 30 subsequent return to baseline.

In contrast, two mice infused with H5.010CMVVL_DLR expressed the VLDL receptor at high levels. The percent of hepatocytes may have decreased slightly as compared to the day 5 mice. These data 5 suggest that the sustained decrease in plasma cholesterol levels in the H5.010CMVVL_DLR-infused mice was due to sustained expression of the VLDL receptor.

Example 6 - Turnover Studies

To further characterize the effects of hepatic 10 VLDL receptor expression on lipoprotein metabolism, turnover studies were performed as follows.

LDL receptor knockout mice were infused with recombinant adenovirus after 3 weeks on the high cholesterol diet as described in Example 4. Three mice 15 each were injected with the lacZ and VLDL receptor adenoviruses; one mouse was injected with the LDL receptor adenovirus. On day 5 post-infusion, mice were injected via the tail vein with approximately 8×10^6 cpm of ^{125}I -labeled human LDL, and 1.6×10^5 cpm of ^{131}I -labeled 20 human VLDL in a total volume of 0.2 ml. A blood sample was obtained 1 minute following injection of radiolabel, and designated the "time zero" sample. Blood was collected into heparinized capillary tubes at the indicated times, and radioactivity remaining was 25 determined using a gamma counter.

Infusion of LDL receptor adenovirus led to accelerated clearance of LDL as compared to infusion of lacZ adenovirus, consistent with a previous study in LDL receptor knockout mice [S. Ishibashi et al, J. Clin. Invest., 92:883-893(1993)]. Similarly, VLDL clearance 30 was accelerated in LDL receptor treated animals as compared to lacZ infused mice. LDL turnover in VLDL receptor-infused mice was indistinguishable from lacZ infused mice, consistent with *in vitro* data which

indicates that LDL is not a ligand for the VLDL receptor [T. Yamamoto et al, Trends in Cardiovascular Medicine, 3:144-148 (1993); F. Batley et al, J. Biol. Chem., 269:23268-23273 (1994)]. VLDL clearance in VLDL receptor infused mice was slightly faster than n lacZ infused mice, but significantly slower than in LDL receptor infused mice.

As discussed above, VLDL turnover in mice infused with the VLDL receptor adenovirus was significantly faster than in lacZ infused mice although the magnitude of this effect was far less than that seen in animals treated with LDL receptor virus. This suggests that VLDL receptor-mediated clearance of circulating VLDL may not be the only pathway leading to diminished serum VLDL. One potential mechanism is secretion-recapture, which occurs with hepatic uptake of chylomicron remnants [T. Willnow & J. Herz, J. Mol. Med., 73:213-220 (1995); H. Shimano et al, J. Clin. Invest., 93:2215-2223 (1994)], and would result in decreased secretion of VLDL and reduced levels of plasma VLDL. A second mechanism may involve the interaction of the VLDL receptor with receptor-associated protein (RAP) [Battey, cited above; H. Mokuno et al, J. Biol. Chem., 269:13238-13243 (1994)] which interacts with a variety of receptors inside the cell, apparently to prevent ligand binding before the receptor reaches the cell surface [G. Bu et al, EMBO J., 14:2269-2280 (1995)]. It is possible that the high levels of VLDL receptor expressed in the livers of adenovirus-infused mice overwhelms the available RAP, so that VLDL receptor is binding to newly synthesized ligand (apoE, either free or in association with lipid) within the cell, and preventing its secretion into the plasma. The effects of hepatic VLDL receptor expression on total plasma cholesterol as well as on lipoprotein

cholesterol levels demonstrate that the VLDL receptor can play a major role in lipoprotein metabolism in vivo.

Example 7 - Stability of Expression of VLDL Receptor

This experiment illustrates relative transgene 5 persistence in mice.

LDL receptor knockout mice were injected intravenously on day 0 with 1×10^{11} particles of H5.010CMVlacZ, H5.010CBhLDLR, or H5.010CMVVLDLR. Mice were sacrificed on the indicated days after injection (3, 10 10 or 21), and fresh-frozen sections of liver were stained with X-gal to detect expression of the lacZ gene, and with anti-LDL receptor antibody or anti-VLDL receptor antibody, followed by a fluorescein-conjugated secondary antibody to detect LDL receptor and VLDL receptor, 15 respectively.

Analysis of liver harvested 3 days after infusion of virus revealed VLDL receptor protein in >80% of hepatocytes; the bright fluorescent signal, which localized to the perimeter of the cell, was absent before 20 gene transfer and in tissues of animals infected with lacZ or LDL receptor containing adenoviruses. Expression of VLDL receptor protein was remarkably stable with recombinant protein detected in approximately 5 to 10% of hepatocytes from tissue harvested 105 days after infusion 25 of virus. This is in striking contrast to the results obtained with lacZ and LDL receptor adenovirus, where expression of the transgene extinguished to undetectable levels within three weeks of gene transfer. VLDL receptor expression remained detectable through the 30 duration of the experiment (22 weeks).

Genomic DNA was isolated from mouse liver, digested with EcoRI, and subjected to Southern blotting [K. Kozarsky et al. J. Biol. Chem., 269:13695-13702 (1994)] to monitor the presence over time of adenoviral

DNA sequences. Adenovirus sequences were detected using the Genius kit from Boehringer Mannheim, followed by chemiluminescent detection. In C57BL/6 mice infused with the lacZ adenovirus, viral DNA diminished rapidly with time, plateauing at barely detectable levels (~0.05 copies/cell) through day 70 post-infusion. Mice infused with VLDL receptor had slightly higher initial levels of DNA, but a similar time course of loss of adenovirus sequences. Additional DNA hybridization studies showed that the majority of adenovirus DNA initially delivered to the liver is not integrated into the mouse genome (data not shown), however, this assay cannot rule out some level of integration.

Histopathologic analysis of liver tissue from mice infused with the VLDL receptor virus revealed inflammation and apoptotic cells at early time points. The timing and extent of the pathologic findings were indistinguishable from liver tissues of mice infused with lacZ and LDL receptor viruses. At 15 and 22 weeks post-infusion, however, liver tissue from VLDL receptor-infused mice displayed discernible accumulations of neutral lipids, as demonstrated by hematoxylin and eosin as well as oil red O staining. Similar changes were observed infrequently in LDL receptor knockout mice infused with PBS, LDL receptor and/or lacZ adenoviruses. No lipid accumulations were observed in livers of normal C57BL/6 mice infused with the VLDL receptor virus, despite long-term transgene expression indistinguishable from that observed in LDL receptor knockout mice. This indicates that VLDL receptor expression alone is not sufficient for the changes in lipid accumulation observed in LDL receptor knockout mice; instead, there is some lipid accumulation in the LDL receptor knockout mice which have been maintained on a high cholesterol diet for

≥ 18 weeks, that is accelerated by prolonged VLDL receptor expression.

Plasma samples from mice infused with VLDL receptor adenovirus were analyzed for the presence of 5 antibodies directed against the VLDL receptor protein. Only one mouse out of twelve generated antibodies to the VLDL receptor despite the presence of high level antibodies to adenovirus capsid proteins in each animal that received virus. Animals infused with the VLDL 10 receptor adenovirus mounted a CTL response to adenoviral proteins indistinguishable from that obtained from animals infused with either lacZ or LDL receptor adenoviruses. These mice, however, did not mount a CTL response to the VLDL receptor protein. Thus, the 15 development of a CTL response to the transgene following infusion of recombinant adenovirus is dependent on the antigenicity of the specific transgene in the treated animal.

Example 8 - Humoral and Cellular Immune Response to
20 Adenovirus and Transgenes

A. *Humoral Immune Response*

Two LDL receptor knockout mice (K020 and K027) or two normal C57BL/6 mice were injected via the tail vein with 1×10^{11} particles of H5.010CBhLDLR at day 0 25 and serum samples were collected both before injection (pre), and on days 10, 24, 39, 52 and 70 following injection for the knockout mice and on day 21 for the C57BL/6 mice. Western blots were performed as previously described [K. Kozarsky et al., *J. Biol. Chem.*, 269:13695- 30 13702 (1994); K. Kozarsky et al., *Som. Cell and Molec. Genet.*, 19:449-458 (1993)]. To detect anti-adenovirus antibodies, purified adenovirus was used as the antigen.

The positive control (+) was rabbit antiserum isolated following intravenous infusion of purified H5.010CBhLDLR.

The negative control (-) was pre-immune rabbit serum.

Western blots with β -galactosidase were performed using

- 5 purified protein (Sigma), with a monoclonal antibody specific for β -galactosidase (Sigma) as a positive control.

Antibodies directed against the human LDL receptor were detected using lysates prepared from 24-23

- 10 cells, a 3T3 cell line which was transduced with retrovirus encoding the human LDL receptor. For detection of anti-VLDL receptor antibodies, a lysate was prepared from HeLa cells two days following infection with H5.010 CMVVLDLR.

15 All mice infused with 1×10^{11} particles of recombinant adenovirus developed antibodies to adenovirus capsid proteins, with major bands corresponding to hexon, penton and fiber. All mice infused with H5.010CBhLDLR developed antibodies to the human LDL receptor protein

- 20 with LDL receptor knockout mice consistently developing higher titer antibodies than C57BL/6 mice. Antibodies from LDL receptor knockout mice cross-reacted with mouse LDL receptor protein, whereas antibodies from C57BL/6 mice (which express normal mouse LDL receptor) did not.

25 This suggests that the VLDL receptor, although the human and not the mouse sequence was used, was not immunogenic in these mice. The amino acid sequences of the human and mouse LDL receptors are approximately 78% identical, while the human and mouse

- 30 VLDL receptors are >94% identical. This increased sequence similarity is likely to account for the absence of antibody development to the human VLDL receptor despite high level expression in the mouse liver as a result of infusion of H5.010CMVVLDLR.

These data demonstrate that animals can generate a humoral immune response specific for the transgene product as well as to the viral proteins encoded on the injected adenovirus. It also provides
5 indirect evidence of antigen specific activation of T helper cells, which is normally required for development of mature, antibody-secreting B cells.

B. Cellular Immune Responses

This study analyzed animals following
10 infusion with the LDL receptor adenovirus for activation of CTLs to both viral antigens and the transgene product, human LDL receptor.

CTL assays were performed as described in Y. Yang et al, Immunity, 1:433-442 (1994). Target cells
15 expressing recombinant vaccinia proteins were generated by infecting with recombinant vaccinia were generated as follows. The VLDV receptor cDNA (in the pRC/CMV plasmid) was subcloned into the HindIII site of Bluescript KS+. The CFTR cDNA [J.R. Riordan et al, Science, 245:1066-1073
20 (1989) was cloned into the PstI site of Bluescript KS+ (Stratagene). The LDL receptor cDNA in the pUC19 vector [T. Yamamoto et al, Cell, 39:27-38 (1984)] was excised with the restriction enzymes HindIII and Sac I and ligated into the HindIII and SacI sites of Bluescript
25 KS+. Each of the cDNAs was then excised using the enzymes SacII and KpnI and cloned into the SacII and KpnI sites of a modified form of the vaccinia expression vector pSC11 [S. Chakrabarti et al, Molec. Cell. Biol., 5:3403-3409 (1985)]. The control recombinant vaccinia,
30 VRG, expresses a rabies virus glycoprotein and was prepared as described in T. Wiktor et al, Proc. Natl. Acad. Sci. USA, 81: 7194-7198 (1984).

CTLs to specific targets were detected in a standard ⁵¹chromium (⁵¹Cr) release assay in which MHC
35 compatible target cells were infected with either

- recombinant adenovirus or vaccinia viruses that express single relevant gene products. Figure 10 presents both an example of a ⁵¹Cr release assay in which % specific lysis is measured as a function of increasing the effector to target ratio (Fig. 10B), as well as a summary of the cumulative data (Fig. 10A). Splenocytes from C57BL/6 mice infused with recombinant adenovirus containing either human LDL receptor or human CFTR were evaluated for their ability to lyse targets infected with either recombinant adenovirus, to measure activity to viral proteins, or with vaccinia virus containing LDL receptor, to measure activity to LDL receptor protein. Cytolytic activity was demonstrated with lymphocytes from animals infected with the LDL receptor virus to target cells infected with the same virus. No cytolysis was detected to mock infected targets supporting the specificity of the assay. These same effector cells demonstrated significant cytolytic activity to targets infected with LDL receptor vaccinia virus that was not present when infected with a control vaccinia. These experiments provide strong evidence for the presence of activated CTL to human LDL receptor in C57BL/6 mice following gene therapy.
- 25 Example 9 - Enhancement of Adenovirus Mediated Gene Transfer upon Second Administration by IL-12 and IFN- γ in Mouse Lung.
- The recombinant adenoviruses H5.010CMVlacZ and H5.010CBALP (alkaline phosphatase gene expressed from the CMV enhanced β -actin promoter in the sub360 backbone) were used in this example. Each similar virus expresses a different reporter gene whose expression can be discriminated from that of the first reporter gene.

Female C57Bl/6 mice (6-8 week old) were infected with suspensions of H5.010CBALP (1×10^9 pfu in 50 μ l of PBS) via the trachea at day 0 and similarly with H5.010CMVlacZ at day 28. One group of such mice was used as a control. Another group of mice were acutely depleted of CD4 $^{+}$ cells by i.p. injection of antibody to CD4 $^{+}$ cells (GK1.5; ATCC No. TIB207, 1:10 dilution of ascites) at the time of the initial gene therapy (days - 3, 0, and +3). A third group of mice were injected with IL-12 (1 μ g intratracheal or 2 μ g, i.p. injections) at the time of the first administration of virus (days 0 and +1). A fourth group of mice were injected with gamma interferon (1 μ g intratracheal or 2 μ g, i.p. injections) at the time of the first administration of virus (days 0 and +1).

When mice were subsequently euthanized and necropsied at days 3, 28, or 31, lung tissues were prepared for cryosections, while bronchial alveolar lavage (BAL) and mediastinal lymph nodes (MLN) were harvested for immunological assays.

A. Cryosections

The lung tissues were evaluated for alkaline phosphatase expression by histochemical staining following the procedures of Y. Yang et al, cited above.

Instillation of alkaline phosphatase virus (10^9 pfu) into the airway of all groups of the C57Bl/6 mice resulted in high level transgene expression in the majority of conducting airways that diminishes to undetectable levels by day 28. Loss of transgene expression was shown to be due to CTL mediated elimination of the genetically modified hepatocytes [Y. Yang et al, cited above].

In the control mice, no recombinant gene expression was detected three days after the second administration of virus, i.e., day 31.

Administration of virus to the CD4⁺ depleted animals was associated with high level recombinant transgene expression that was stable for a month. Expression of the second virus was detectable on 5 day 31.

Initial high level gene transfer diminished after about one month in the IL-12 treated mice; however, in contrast to the control, high level gene transfer to airway epithelial cells was achieved 10 when virus was readministered to IL-12 treated animals at day 28, as seen in the day 31 results.

The gamma-interferon treated animals were virtually indistinguishable from the animals treated with IL-12 in that efficient gene transfer was accomplished 15 upon a second administration of virus.

B. *Immunological Assays - MLN*

Lymphocytes from MLN of the control group and IL-12 treated group of C57Bl/6 mice harvested 28 days after administration of H5.010CBALP were restimulated in 20 vitro with UV-inactivated H5.010CMVlacZ at 10 particles/cell for 24 hours. Cell-free supernatants were assayed for the presence of IL-2 or IL-4 on HT-2 cells (an IL-2 or IL-4-dependent cell line) [Y. Yang et al, cited above]. Presence of IFN- γ in the same lymphocyte culture 25 supernatant was measured on L929 cells as described [Y. Yang et al, cited above]. Stimulation index (S.I.) was calculated by dividing ^3H -thymidine cpm incorporated into HT-2 cells cultured in supernatants of lymphocytes restimulated with virus by those incorporated into HT-2 30 cells cultured in supernatants of lymphocytes incubated in antigen-free medium.

The results are shown in Table 1 below.

Table 1

| | | ³ H-Thymidine Incorporation (cpm±SD) | | IFN- γ liter |
|----|----------------------|---|-----------|----------------------|
| | Medium | H5.010CMVlacZ | S.I. | (IU/ml) ^a |
| 5 | C57Bl/6 | 175 ± 40 | 2084 ± 66 | 11.91 |
| | anti-IL2 (1:5000) | | 523 ± 81 | 2.98 |
| 10 | anti-IL4 (1:5000) | | 1545 ± 33 | 8.83 |
| | C57Bl/6 +IL12 | 247 ± 34 | 5203 ± 28 | 21.07 |
| 15 | anti-IL2 (1:5000) | | 776 ± 50 | 3.14 |
| | anti-IL4 (1:5000) | | 4608 ± 52 | 18.66 |

Stimulation of lymphocytes from regional
 20 lymph nodes with both recombinant adenoviruses led to secretion of cytokines specific for the activation of both T_{H1} (i.e., IL-2 and IFN- γ) and T_{H2} (i.e., IL-4) subsets of T helper cells (Table 1).

Analysis of lymphocytes from the IL-12
 25 treated animals stimulated *in vitro* with virus revealed an increased secretion of IL-2 and IFN- γ and a relative decreased production of IL-4 as compared to animals that did not receive IL-12 (i.e., ratio of IL-2/IL-4 was increased from 3 to 6 when IL-12 was used; Table 1).

30 C. Immunological Assays - BAL

BAL samples obtained from animals 28 days after primary exposure to recombinant virus were evaluated for neutralizing antibodies to adenovirus and anti-adenovirus antibody isotypes as follows. The same
 35 four groups of C57Bl/6 mice, i.e., control, CD4⁺

depleted, IL-12 treated and IFN- γ treated, were infected with H5.010CBALP. Neutralizing antibody was measured in serially diluted BAL samples (100 μ l) which were mixed with H5.010CMVlacZ (1×10^6 pfu in 20 μ l), incubated for 5 1 hour at 37°C, and applied to 80% confluent HeLa cells in 96 well plates (2×10^4 cells per well). After 60 minutes of incubation at 37°C, 100 μ l of DMEM containing 20% FBS was added to each well. Cells were fixed and stained for β -galactosidase expression the following day.

10 All cells were lacZ positive in the absence of anti-adenoviral antibodies.

Adenovirus-specific antibody isotype was determined in BAL by using enzyme-linked immunosorbent assay (ELISA). Briefly, 96-well plates were coated with 15 100 μ l of PBS containing 5×10^9 particles of H5.010CMVlacZ for 18 hours at 4°C. The wells were washed 5 times with PBS. After blocking with 200 μ l of 2% BSA in PBS, the plates were rinsed once with PBS and incubated with 1:10 diluted BAL samples for 90 minutes at 20 4°C. Thereafter, the wells were extensively washed and refilled with 100 μ l of 1:1000 diluted alkaline phosphatase-conjugated anti-mouse IgG or IgA (Sigma). The plates were incubated, subsequently washed 5 times, and 100 μ l of the substrate solution (p-nitrophenyl phosphate, PNPP) was added to each well. Substrate conversion was stopped by the addition of 50 μ l of 0.1M EDTA. Plates were read at 405 nm.

25 The results are shown graphically in Figs. 11A through 11C, which summarize neutralizing antibody titer, and the relative amounts (OD_{405}) of IgG and IgA present in BAL samples. The titer of neutralizing antibody for each sample was reported as the highest dilution with which less than 50% of cells stained blue.

As demonstrated in the first bar of Figs. 11A through 11C, the cytokines identified in Table 1 above were associated in the control mice with the appearance of antibodies to adenovirus proteins in BAL of 5 both the IgG and IgA isotypes that were capable of neutralizing the human Ad5 recombinant vector in an *in vitro* assay out to a 1:800 dilution.

As shown in the second bar of the graphs of Figs. 11A through 11C, transient CD4⁺ cell depletion 10 inhibited the formation of neutralizing antibody (Fig. 11A) and virus specific IgA antibody (Fig. 11C) by 80-fold, thereby allowing efficient gene transfer to occur following a second administration of virus. Fig. 11B shows a slight inhibition of IgG as well.

More importantly, as shown in the third 15 bar of the three graphs, IL-12 selectively blocked secretion of antigen specific IgA (Fig. 11C), without significantly impacting on formation of IgG (Fig. 11B). This was concurrent with a 32-fold reduction in 20 neutralizing antibody (Fig. 11A).

The gamma-interferon treated animals (fourth bar of Figs. 11A through 11B) were virtually indistinguishable from the animals treated with IL-12 in 25 that virus specific IgA (Fig. 11C) and neutralizing antibody (Fig. 11A) were decreased as compared to the control animals not treated with cytokine, but not to the extent obtained with those treated with IL-12.

These studies demonstrate that inhibition 30 of CD4⁺ function at the time of primary exposure to virus is sufficient to prevent the formation of blocking antibodies. The concordant reduction of neutralizing antibody with antiviral IgA suggests that immunoglobulin of the IgA subtype is primarily responsible for the blockade to gene transfer.

All references recited above are incorporated herein by reference. Numerous modifications and variations of the present invention are included in the above-identified specification and are expected to be
5 obvious to one of skill in the art. Such modifications and alterations to the compositions and processes of the present invention, such as selections of different modifications of adenovirus vectors selected to carry the VLDLR gene, or selection or dosage of the vectors or
10 immune modulators are believed to be within the scope of the claims appended hereto.

WHAT IS CLAIMED IS:

1. A recombinant viral vector comprising:
 - (a) the DNA of, or corresponding to, at least a portion of the genome of an adenovirus, which portion is capable of infecting a hepatic cell;
 - (b) a human VLDL receptor gene operatively linked to regulatory sequences directing its expression, said gene flanked by the DNA of (a) and capable of expression in the hepatic cell.
2. The vector according to claim 1 wherein said adenovirus DNA comprises the adenovirus 5' and 3' cis-elements necessary for replication and virion encapsidation in the absence of sequence encoding viral genes.
3. The vector according to claim 1 or 2 wherein said adenovirus genome has a deletion in all or a part of the E1 gene.
4. The vector according to any of claims 1 to 3 wherein said adenovirus genome has a deletion in all or a part of the E3 gene.
5. The vector according to any of claims 1 to 3 wherein said adenovirus genome comprising deletions in the DNA sequences of all or a portion of the adenovirus genes selected from the group consisting of the E2a gene, the E4 gene, the late genes L1 through L5, the intermediate genes IX and IV, and a combination thereof.
6. A mammalian hepatocyte which expresses a human VLDL receptor gene introduced therein through transduction of the vector of any one of claims 1 to 5.

7. Use of a recombinant viral vector for the manufacture of a medicament, said viral vector comprising:

- (a) the DNA of, or corresponding to, at least a portion of the genome of an adenovirus, which portion is capable of infecting a hepatic cell;
- (b) a human VLDL receptor gene operatively linked to regulatory sequences directing its expression, said gene flanked by the DNA of (a) and capable of expression in the hepatic cell.

8. The use according to claim 7 wherein the medicament is used for reducing cholesterol levels in familial hypercholesterolemia patients.

9. The use according to claim 7 wherein the medicament is used for reducing cholesterol levels in familial combined hyperlipidemia patients.

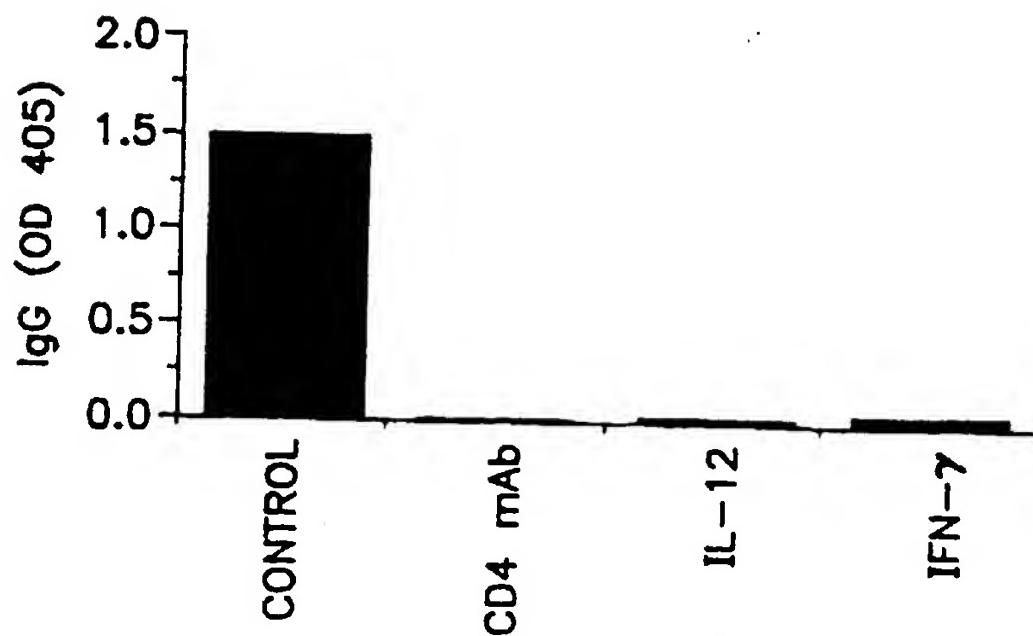

FIG. IIC

INTERNATIONAL SEARCH REPORT

International application No

PCT/US 96/03041

A. CLASSIFICATION OF SUBJECT MATTER

IPC 6 C12N15/86 C12N5/10 A61K38/17 //C07K14/705

According to International Patent Classification (IPC) or to both national classification and IPC

B. FIELDS SEARCHED

Minimum documentation searched (classification system followed by classification symbols)
IPC 6 C12N A61K C07K

Documentation searched other than minimum documentation to the extent that such documents are included in the fields searched

Electronic data base consulted during the international search (name of data base and, where practical, search terms used)

C. DOCUMENTS CONSIDERED TO BE RELEVANT

| Category * | Citation of document, with indication, where appropriate, of the relevant passages | Relevant to claim No. |
|------------|--|-----------------------|
| A | JOURNAL OF BIOLOGICAL CHEMISTRY, vol. 269, no. 18, 6 May 1994, MD US, pages 13695-13702, XP002007097 K.F.KOZARSKY ET AL.: "In vivo correction of low density lipoprotein receptor deficiency in the Watanabe heritable hyperlipidemic rabbit with recombinant adenoviruses" cited in the application see the whole document --- -/- | 1-9 |

 Further documents are listed in the continuation of box C. Patent family members are listed in annex.

* Special categories of cited documents :

- 'A' document defining the general state of the art which is not considered to be of particular relevance
- 'E' earlier document but published on or after the international filing date
- 'L' document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)
- 'O' document referring to an oral disclosure, use, exhibition or other means
- 'P' document published prior to the international filing date but later than the priority date claimed

- 'T' later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention
- 'X' document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone
- 'Y' document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art
- '&' document member of the same patent family

1

Date of the actual completion of the international search

1 July 1996

Date of mailing of the international search report

25.07.96

Name and mailing address of the ISA

European Patent Office, P.B. 5818 Patentlaan 2
NL - 2280 HV Rijswijk

Cupido, M

INTERNATIONAL SEARCH REPORT

Application No.
PCT/US 96/03041

C(Continuation) DOCUMENTS CONSIDERED TO BE RELEVANT

| Category | Citation of document, with indication, where appropriate, of the relevant passages | Relevant to claim No. |
|----------|---|-----------------------|
| A | THE JOURNAL OF CLINICAL INVESTIGATION, vol. 92, no. 2, August 1993, pages 883-893, XP000574730 S.ISHIBASHI ET AL.: "Hypercholesterolemia in low density lipoprotein receptor knockout mice and its reversal by adenovirus-mediated gene delivery" cited in the application --- | 1-9 |
| A | SOMATIC CELL AND MOLECULAR GENETICS, vol. 19, no. 6, November 1993, pages 557-569, XP000574726 M-E-GAFVELS ET AL. : "Cloning of a cDNA encoding a putative human very low density lipoprotein/apolipoprotein E receptor and assignment of the gene to chromosome 9pter-p23" cited in the application see the whole document --- | 1-9 |
| A | HUMAN MOLECULAR GENETICS, vol. 3, no. 4, April 1994, OXFORD GB, pages 531-537, XP002007098 J.C.WEBB ET AL.: "Characterization and tissue-specific expression of the human 'very low density lipoprotein (VLDL) receptor' mRNA" see the whole document ----- | 1-9 |
